Summary

1. There is relatively little information on how evolutionary processes that alter genetic variation in a focal species may affect interactions with other species, impact the structure or function of the community and ecosystem, and affect evolutionary feedbacks among interacting species through time.

2. Because evolution can occur at ecological time-scales, it is important to understand how major selective events, such as climatic changes, can impact the community of interacting species and ecosystem processes by changing intraspecific genetic variation.

3. The evidence linking genetic variation and evolution to community change and feedbacks has arisen from several different approaches whose results have not been synthesized into one conceptual framework, and whose commonalities may not be fully understood.

4. This review synthesizes several different experimental approaches on how evolution may impact communities and ecosystems and focuses on five main issues: (i) the genetic basis to communities and ecosystems; (ii) the community and ecosystem consequences of among-population genetic differentiation; (iii) the role of local adaptation and co-evolution; (iv) the effects of transgenerational feedbacks and the eco-evo dynamic and; (v) the integration of community and ecosystem genetics and multi-level selection.

5. Evolution can alter intraspecific genetic variation to affect indirect genetic effects and feedbacks. Future studies should investigate how communities and ecosystems are affected when evolution causes the strength of feedbacks to change.

Key-words: co-evolution, community and ecosystem genetics, eco-evo interactions, feedbacks, genes to ecosystems, genetic differentiation, genetic variation, multi-level selection, Price equation

Introduction

An important current issue in community and ecosystem genetics research is determining the relevance of intraspecific genetic variation (i.e. polymorphism) and genetic differentiation (i.e. divergence) (Table 1) to ecological and evolutionary processes at the community and ecosystem level. Intraspecific genetic variation in a focal species not only affects the composition of associated communities, but can cause community members to evolve in response to genetic differentiation across the focal species' range, which provides a strong argument for the necessity of considering intraspecific genetic variation in ecological studies. The genetic analysis of ecological and evolutionary interactions involving multiple species may seem complicated, because community and ecosystem phenotypes represent complex traits related to genetically based interactions among species, and because abiotic and biotic environmental variation have a large effect on their expression. However, in both controlled common garden environments and across broad biogeographic regions, genetic variation in one species can have predictable and heritable effects on associated communities and ecosystems (Whitham et al. 2003, 2006; Johnson & Stinchcombe 2007; Bangert et al. 2008; Bailey et al. 2009; Johnson, Vellend & Stinchcombe 2009). It is crucial that we further our understanding of these processes, because when genetic variation in one species drives the expression of community and ecosystem phenotypes, selection can alter...
that genetic variation, resulting in evolution in one species which will further affect associated communities and ecosystems (Bailey et al. 2011).

The attempt to understand how evolution acts on genetic variation within a species to affect associated communities is not a new endeavour – for decades, both ecologists and evolutionary biologists have been interested in understanding how evolution in one species affects other species in the community (e.g. Pimentel 1961, 1968; Janzen 1980; Reznick & Endler 1982; Antonovics 1992; Thompson 1998; Grant & Grant 2002; Whitham et al. 2006). For example, Pimentel (1968) proposed that evolution in one species could regulate the population of another through a ‘genetic feedback mechanism’ through which the selective pressure on host plants increases with herbivore densities, causing changes in the genetic makeup of the host populations such that they become more resistant. This change, in turn, imposes selection on herbivores to overcome plant resistance. Moreover, it has been clearly shown that evolution can occur at ecologically relevant time-scales (Thompson 1998; Hendry & Kinnison 1999; Bohannan & Lenski 2000; Kinnison & Hendry 2001; Grant & Grant 2002; Yoshida et al. 2003; Hairston et al. 2005) and this observation is a unifying element to every approach linking ecology and evolution, including the geographic mosaic theory of co-evolution (Thompson 1999), diffuse co-evolution (Janzen 1980; Fox 1981; Herrera 1982; Strauss, Sahli & Connor 2005; Wade 2007), community heritability (Whitham et al. 2003, 2006; Shuster et al. 2006), and eco-evo feedbacks (Post & Palkovacs 2009). This has important implications because it suggests that major selective events such as climate change, increased habitat fragmentation, and species invasions can have extended ecological consequences by changing intraspecific genetic variation. While rapid evolution has already been incorporated into invasion biology through the ‘evolution of increased competitive ability’ hypothesis (see review by Bossdorf et al. 2005) and the ‘hybridization increases invasiveness’ hypothesis (see review by Ellstrand & Schierenbeck 2000) the demonstration that rapid evolution can alter species interactions and ecosystem properties has broad implications that are not commonly addressed in many other subfields of ecology including conservation biology, plant-pollinator interactions, and restoration ecology.

Although decades of research clearly shows that intraspecific genetic variation has community-level consequences, the extent to which evolutionary forces change genetic variation in one species and affect associated communities, and whether these changes feed back to affect the original species, is less clear. One conceptual model for understanding the extended effects of evolution acting on intraspecific genetic variation involves expanding Lewontin’s (1974) representation of population genetic transformations occurring in genotype and phenotype space to include another level of ‘community space’ (Fig. 1). In this diagram, ‘spaces’ represent a set of possible values for genotypes, phenotypes, and communities, respectively, and arrows represent the ‘transformations’ between different spaces. For example, the transformation beginning in genotype space and ending in phenotype space represents the results of different genotypes developing in various environments (Lewontin 1974). In the expanded version the transformation beginning in phenotype space and ending in community space represents the community phenotype of genes being expressed by the species of interest. In this model, we assume that all community-level effects of genotype are mediated through the expressed phenotypes. In some systems, intraspecific genetic variation may have little or no effect on associated communities (Fig. 1a), suggesting that other ecological factors determine community composition. For example, Tuck et al. (2010) reported that insect communities associated with Quercus robur were determined more by an environmental factor, spatial connectivity, than by...
host-plant genotype. When intraspecific genetic variation does affect associated communities, then evolution can lead to changes in the associated community (Fig. 1b), represented by transformations between the phenotype and community spaces. Transformations can also begin in community space and end in phenotype space, if the community represents an environmental factor driving differences in an organism’s phenotype independent of genetics (Fig. 1c). In some cases, evolution in a community context will feed back to affect the fitness and performance of the focal species (Fig. 1d). In this case, the transformation in phenotype space (dashed arrow) is primarily driven by the transformation in

Although ecological feedbacks in natural systems are just beginning to be formally studied at the genetic level (e.g. *Lankau & Strauss 2007; Pregitzer et al.* 2010), studies of this nature have broad implications to many scientific disciplines, some of which currently do not incorporate genetic variation as a part of their research. Many types of feedbacks exist, but a common feature is that feedbacks occur when an organism modifies its abiotic (e.g. increased leaf area causes decreased ground temperature) or biotic (e.g. changes in prey community structure due to predation pressure) environment, and that modification in turn affects the fitness of the organism or other community members (Van der Putten, VanDijk & Peters 1993; Bever 1994; Jones, Lawton & Shachak 1997; *Post & Palkovacs* 2009). Feedbacks are fundamental to the co-evolutionary process (Thompson 2005) and local adaptation (Clausen, Keck & Hiesey 1940; Gandon & Nuismer 2009) because in each of these cases the interacting species can exert reciprocal fitness consequences. Additionally, feedbacks are an important part of the maintenance of biodiversity (Bascompte & Jordano 2007; *Lankau & Strauss* 2007; *Duffy & Forde* 2009; *Laine* 2009). For example, in a recent review, *Laine* (2009) reported that variation in the strength of feedbacks led to population-level divergence in the traits of interacting species. Finally, there has been virtually no consideration of the extended consequences of particular feedbacks in community or ecosystem ecology; for example, if a feedback alters the fitness and performance of one species, how does that alter interactions with other species and the ecosystem services they mediate? Although recent studies have begun to address the dynamic nature of ecological and evolutionary feedbacks (e.g. *Lankau & Strauss* 2007; *Palkovacs & Post* 2008; *Pregitzer et al.* 2010), a more complete understanding of these feedbacks remains a major challenge.
As the field of community and ecosystem genetics is currently focused on documenting the extended effects of genetic variation in a focal species, this review provides a broad conceptual framework for understanding how evolution may impact communities and ecosystems. We discuss five main elements relating to ‘genes to ecosystems’ research, including: (i) intraspecific genetic variation affects communities and ecosystems, although these effects can be dependent on abiotic and biotic environmental context; (ii) evolution in one species across its native range leads to genetic differentiation which affects associated communities; (iii) genetically differentiated populations of species can co-evolve interactions with other species which maximize the focal species’ fitness in a given environment; (iv) genetically differentiated populations can affect the success of subsequent generations of their offspring and the offspring of other community members through trans-generational feedbacks; and finally, (v) feedbacks may vary in space and time and may be a consequence of the community of interacting species or even the ecosystem processes that those communities mediate (Lankau & Strauss 2007; Bailey et al. 2009). This suggests that the relative fitness of any individual may vary depending upon characteristics of the specific ‘group’ (i.e., population, community, and ecosystem) to which it belongs and suggests that concepts associated with multi-level selection may be useful for understanding the potential impacts of selection on populations as a consequence of the particular ‘groups’ with which they are associated. In this last section, we use the Price equation to define mathematically how multi-level selection may act within the context of the community and ecosystem. In this review, we attempted to bring together these five components whose synthesis suggests that if the evolutionary dynamic in a system changes, then the ecological dynamic also likely changes (and vice versa) through indirect genetic effects and feedbacks, with consequences that can extend from the phenotype of an individual within a population to affect associated communities and ecosystem processes. Our examples largely focus upon plant-herbivore interactions, but the ideas and conceptual framework proposed are general and may apply to any system.

**Genetic basis to communities and ecosystems**

Linking genetic variation within species to patterns and processes that occur above the population level is critical to understanding how genetic changes in one species may affect the ecology of associated species (Bailey et al. in press). One approach to this problem involves quantifying the predictability of community and ecosystem responses with respect to genetic factors in a given species. A common experimental approach to this question has been to collect plants from a specific population and then to plant all collected specimens in a ‘common garden’ at one location. Within the common garden, trait differences across genotypes can be assessed in the absence of high environmental variation. Common garden studies have been instrumental in building our understanding of the extended effects of genotypic variation on traits at the community (Whitham et al. 2003, 2006; Johnson & Agrawal 2005; Bailey et al. 2006; Crutsinger et al. 2006; Johnson, Lajeunesse & Agrawal 2006; Tetard-Jones et al. 2007; see also Fig. 1a), and ecosystem (Whitham et al. 2003, 2006; Crutsinger et al. 2006; Madritch, Donaldson & Lindroth 2006; Schweitzer et al. 2008; Pregitzer et al. 2010) level. However, the effects of genetic variation on associated communities are often context dependent, varying across different environments [genetic (G) × environment (E) interactions, e.g. Johnson & Agrawal 2005; Bangert et al. 2008; Bossdorf, Shuja & Banta 2009] or due to the presence of genetic variation in other species in addition to non-genetic biotic and abiotic environmental effects (G × G × E interactions, e.g. Tetard-Jones et al. 2007). For example, Tetard-Jones et al. (2007) manipulated aphid and barley genotypes, and showed that the presence of rhizobacteria significantly altered the genotype by genotype interactions between aphids and barley. Genetic by environment interactions are important because the context dependency of genetic effects sets up the possibility of community-level responses to genetic differentiation and local adaptation if a species’ range includes many different environments. These interactions also suggest that studies of genetic cline along elevational or latitudinal gradients could improve our knowledge of how strong the effects of genetic variation and differentiation are in the context of varying environmental conditions (Bailey et al. in press).

The higher-level ecological effects of genetic variation were first termed ‘extended phenotypes’ by Dawkins (1982) because they are caused by the expression of genes in an individual. Extended phenotypes have been further characterized as community and ecosystem phenotypes, respectively, which describe the tendency for genetically related individuals to support similar communities and affect ecosystem processes in similar ways (Whitham et al. 2003, 2006). A common garden experimental framework allows the estimation of variation in the community or ecosystem phenotype and the extent to which it is explained by variation in underlying genetic factors. The heritability of community phenotypes involves using traditional diversity indices (i.e. Simpson’s or Shannon–Weiner) or an ordination technique to convert multivariate community data (associated with individuals of a focal species) into a univariate response which can be analyzed with standard statistical tools, allowing for the estimation of the broad sense heritability of community traits (see Johnson & Agrawal 2005; Shuster et al. 2006; Whitham et al. 2006 for details). For example, in *Populus* spp., the heritability of communities associated with particular genotypes has been estimated as 0.56–0.63 for arthropod communities and 0.70 for soil microbial communities or microbial pools of nutrients (Shuster et al. 2006; Schweitzer et al. 2008).

Many investigators argue that community and ecosystem phenotypes represent complex traits related to variation in the fitness consequences of indirect genetic effects (IGEs) among species (Thompson 2005; Shuster et al. 2006; Whitham et al. 2006; Tetard-Jones et al. 2007). In their most basic form, IGEs are environmental influences of genes in one individual on the phenotype and fitness of an associated
conspecific individual (Moore, Brodie & Wolf 1997; Agrawal, Brodie & Wade 2001). When IGEs occur between different species, they are referred to as interspecific IGEs (IGEs, Shuster et al. 2006; Whitham et al. 2006). Based on theory outlined by Shuster et al. (2006), genetically based variation in community phenotypes provides evidence that: (i) fitness effects arise due to IGEs, and (ii) through differential fitness consequences of IGEs, selection can occur in a community context. While it has been suggested that a finding of significant community heritability provides evidence of evolution in a community context, in practice, the relationship between community heritability and co-evolution by natural selection is less clear.

For associated species to evolve in response to underlying plant genetic variation there are four important requirements. First, plant genotypes have to act as an agent of selection affecting the fitness and phenotype of the associated species (described in the preceding paragraphs). Second, the effects of plant genetic variation on arthropods must be mediated by genetic variation for arthropod traits (Lewontin 1970). Third, the variation in arthropod traits must also covary with arthropod fitness (Lewontin 1970). Fourth, some spatial isolation or other mechanism is required to prevent gene flow between populations that are evolving in response to different selective environments (i.e. associations with different host plant genotypes). For example, Heschel & Paige (1995) showed that introducing pollen from a larger population of scarlet gilia (Ipomopsis aggregata) to a smaller population was enough to ease extinction risk caused by small population size, illustrating the well-known principle that even very low levels of gene flow can have relatively large effects on the genetic structure of populations (Wright 1931; Hartl & Clark 1997). Although divergent adaptation in the face of gene flow is possible, and often observed in phytophagous insects (see reviews by Dres & Mullet 2002; Coyne & Orr 2004; Bolnick & Fitzpatrick 2007), the conditions are restrictive (Lenormand 2002) and the strength of selection needed to overcome gene flow might be rare among genotypes of a single host plant population (but see Van Zandt & Mopper 1998). Immigration can affect the rate at which arthropod populations became locally adapted to host plant genotypes. For example, Tack & Roslin (2010) reported that arthropod abundance was higher on local genotypes of Quercus robur, compared to genotypes transplanted from different parts of the species’ range, when immigration rates were low; however, the opposite pattern was observed (higher arthropod abundance on transplanted genotypes than local genotypes) when immigration rates were high. The effects of immigration on community heritability are important because most estimates of community heritability are from within a single common garden site where gene flow among the pool of possible herbivore populations is not limited. A better understanding of how genetic variation in one species affects associated community members requires that experiments are carried out at larger spatial scales (i.e. along environmental gradients or among races) such that realistic levels of gene flow can be compared with the effects of selection.

Community and ecosystem consequences of among population genetic differentiation

Identifying and understanding genetic differentiation along specific environmental gradients (Endler 1977; Storfer 1999; Foster et al. 2007) provides an important tool for addressing the hypothesis that evolution in one species can lead to change at the community and ecosystem level. One promising approach to examining how evolution in one species leads to change in associated communities and ecosystem processes involves investigating whether a species is genetically differentiated across its geographic range and then determining whether that genetic differentiation has affected associated communities and ecosystem processes. For example, in a 15-year-old plantation forest trial, Barbour et al. (2009a) found that (i) genetically based variation in Eucalyptus globulus expressed at the race and family level was correlated with differences in the associated arthropod community; (ii) community divergence among races was correlated with leaf physical and chemical traits; and (iii) community dissimilarity was correlated with neutral marker and quantitative genetic dissimilarity. Because variation among populations as well as between families was detected, this indicates that E. globulus had genetically differentiated across its range, and that this differentiation had led to changes in the associated community. This type of experiment is represented in Fig. 1b, in which the transformations in genotype and phenotype space represent the process of genetic differentiation, and the subsequent transformations in community space represent the unique community composition of each family of E. globulus. Using the same plantation forest, differences among races in litter arthropod communities (Barbour et al. 2009b) and soil nitrate (NO3−) availability (Bailey et al. 2011) were also detected, demonstrating broad community and ecosystem phenotypes of E. globulus. Genetic differentiation along latitudinal gradients can also affect plant palatability to herbivores (B. T. Moles, S. P. Bonser, I. R. Wallis & W. J. Foley, unpublished data). For example, Pennington, Siska & Bertness (2001) allowed herbivorous insects to choose between conspecific plants collected from northern and southern environments within the United States and reported that herbivores preferred the northern plants, a pattern which held across herbivore species. These studies indicate that genetic differentiation across broad geographic ranges can result in variation to foliar and litter arthropod communities and soil nitrogen availability (Bailey et al. 2011). Based on theory established in Shuster et al. (2006), one may expect that community differences resulting from divergence in one species (e.g. E. globulus) suggest that all interacting species are differentiating in a co-evolutionary manner. However, the frequency and intensity of co-evolution will vary; co-evolution is most likely to be observed when the strength of feedbacks is large relative to gene flow. Because genetic variation interacts with differences in the regional species pool, strong inferences about the co-evolutionary dynamics are difficult to make without placing the differenti-
ated population (e.g. *E. globulus*) within all potential communities to test for feedbacks (see local adaptation below).

Another way that evolution can affect change in associated communities is reticulate evolution, which can occur in hybridizing species complexes. In *Populus* (*P. angustifolia* X *P. fremontii*), Bailey et al. (in press) showed that introgression at a single molecular marker had important effects on associated arthropod communities; for example, total arthropod richness increased by 23% and gall-forming arthropod abundance increased by 72% on trees carrying the *P. fremontii* allele at the molecular marker RFLP-755. Introgression also caused a 56% increase in ramet production and a 51% decrease in the production of salicortin, an anti-herbivore defensive compound (Palo 1984; Rehill et al. 2006; Bailey et al. 2007). A multiple regression model indicated ramet production, but not salicortin, predicted arthropod abundance, suggesting that the increase in arthropod abundance was due to increased vegetative branching (Price 1991). Reticulate evolution can also lead to the evolution of invasiveness by introduced species (see review by Ellstrand & Schierenbeck 2000), which is important because of the large effects these invaders can have on associated communities and ecosystems. For example, invasion by a hybrid cordgrass, *Spartina alterniflora* × *foliosa*, affected sediment properties and associated communities, increasing sediment organic matter and decreasing benthic macrofaunal density by 75% (Neira, Levin & Grosholz 2005). These results indicate that community phenotypes can be sensitive to even small genetic changes, suggesting that evolutionary changes in associated communities may occur more often, and through a simpler mechanism, than previously thought.

Genetic variation may be expressed and evolutionary processes may act in a variety of ways to affect patterns of community structure and ecosystem function. Moreover, there is emerging evidence from a variety of taxa, including vertebrates (e.g. Palkovacs & Post 2008), which clearly indicates that evolutionary dynamics can operate on ecological timescales (Thompson 1998; Hendry & Kinnison 1999; Bohannan & Lenski 2000; Kinnison & Hendry 2001; Grant & Grant 2002; Yoshida et al. 2003; Hairston et al. 2005). While genetic variation in one species can have community and ecosystem consequences, little is understood about whether there are feedbacks from the community or ecosystem on the fitness and performance of a focal population, and how these feedbacks may affect ecological and evolutionary dynamics.

**Local adaptation, the co-evolutionary process, and feedbacks**

Genetic differentiation that is a result of natural selection commonly results in strong patterns of local adaptation. Local adaptation occurs when individuals born in a given habitat have higher fitness within that habitat (i.e. ‘home’ environment), than individuals from other habitats (i.e. ‘away’ environments). Such local adaptation may be associated with factors such as differences in temperature or precipitation along elevational or latitudinal gradients. For example, Clausen, Keck & Hiesey (1940) showed that clones of sticky cinquefoil (*Potentilla glandulosa*) performed better when grown near their native elevation than at other elevations, suggesting that the populations were adapted to local abiotic environmental conditions.

Local adaptation can also occur in response to biotic environmental variation, and this type of local adaptation can result in the co-evolutionary process. Local adaptation associated with biotic environmental variation is largely associated with species interactions which vary across a species’ range (Pennings, Siska & Bertness 2001; Thompson 2005; Johnson et al. 2010; Bailey et al. 2011). For example, Johnson et al. (2010) collected ecotypes of *Andropogon gerardii* from across its range and planted them in *all home and away* conditions with respect to both soils and arbuscular mycorrhizal (AM) fungi communities to maximize transfer of the most limiting nutrients between plants and fungi. Because this study manipulated ecotype identity in ‘all possible home and away’ environments from which individuals were collected, it confirms that subpopulations of *A. gerardii* had both genetically differentiated and co-evolved interactions with particular AM fungi strains in different environments across its range. However, the ‘all possible home and away’ approach can be financially and logistically intractable depending upon the number of families collected from each population, the number of populations sampled across the range of the species and the number of different abiotic and biotic environments that are tested (Barbour et al. 2009a).

When local adaptation and co-evolution are detected in genetically differentiated populations (e.g. Johnson et al. 2010), genetically based feedbacks can be inferred because certain populations display greater fitness and performance in their ‘home’ environment (biotic and abiotic) vs. an ‘away’ environment. When a population performs better in its home environment relative to away conditions it experiences a positive feedback. When a population performs better under away conditions, it experiences a negative feedback. Similar to the design of local adaptation studies, experiments to test for feedbacks would be conducted by establishing common gardens at every location from which a subpopulation was collected; however, in contrast to local adaptation studies, feedback studies examine the dynamic nature of organisms’ modifying their environment and the fitness consequences of those modifications.

Feedbacks could be observed in a variety of species interactions, including those between plants and herbivores, plants and their soil communities, plants and neighbouring plants, animals and their prey, and many others. It is likely that species experience multiple positive and/or negative feedbacks from many different interactions simultaneously, and understanding how multiple feedbacks may interact is largely uninvestigated. For example, a plant may experience a positive feedback in genotype monocultures because it is able to
cultivate a specific microbial community below-ground (Johnson et al. 2010); conversely, a plant may experience a negative feedback in a genotype mixture due to temporal and spatial partitioning of resource acquisition (Crutsinger et al. 2006). Theoretically, feedbacks with fitness consequences are implicit in the measurement of the heritability of community composition because different communities are assumed to have different fitness consequences for any given species. However, quantification of such feedbacks requires the experimental manipulation of the associated community and the subsequent measurement of the original species’ fitness and performance. Furthermore, even if plant fitness and performance change with the removal of the associated community, understanding the strength of the feedback through time is an additional challenge.

**Trans-generational feedbacks and the eco-evo dynamic**

Feedbacks involving reciprocal interactions of ecology and evolution over relatively short time-scales have been termed eco-evo feedbacks, which are defined as occurring when a population alters its environment (abiotic or biotic) and those environmental changes influence the fitness of the original population (Post & Palkovacs 2009) or subsequent generations (i.e. trans-generational feedback, Pregitzer et al. 2010). While community and ecosystem phenotypes clearly indicate the potential of feedbacks to occur between associated species, simply detecting a community or ecosystem phenotype does not specifically examine such interactions or speak to the dynamic nature of eco-evo feedbacks. Intraspécific genetic variation provides a means for testing how eco-evo feedbacks affect species and their environments through time, although it is not technically a prerequisite condition for eco-evo feedbacks to occur (Post & Palkovacs 2009).

Examples of systems with a high potential for eco-evo feedbacks include those in which intraspecific genetic variation is high (Yoshida et al. 2003) or species interactions are continuous throughout the year, rather than intermittent (Palkovacs & Post 2008). One example of eco-evo feedbacks comes from Lankau & Strauss (2007), who showed that genetic variation for sinigrin content in *Brassica nigra* is responsible for a feedback which maintains diversity in plant communities, due to an intransitive (i.e. rock-paper-scissors) competitive relationship in which high-sinigrin *B. nigra* individuals can invade patches of heterospecific neighbours, low-sinigrin *B. nigra* individuals can invade patches of high sinigrin *B. nigra*, and heterospecific neighbours can invade patches of low-sinigrin *B. nigra*. This result indicates that genetic variation for sinigrin content is responsible for feedbacks which maintain genetic diversity in *B. nigra*, and species diversity in neighbouring plants. This type of experiment is represented in Fig. 1d, in which genetic variation in *B. nigra* for sinigrin content drives changes in the associated plant community, which in turn affects which genotypes of *B. nigra* will perform well in the next generation. While we recognize that *B. nigra* may reduce the species diversity by outcompeting its neighbours in some cases, we discuss this study to illustrate the potential for genetic differentiation to cause community changes which feedback to affect traits in the original species.

Another mechanism through which transgenerational feedbacks can operate involves offspring performing better in their parent’s soil than in an ‘away’ soil environment. For example, Pregitzer et al. (2010) showed that *P. angustifolia* seedlings performed better when grown in soil conditioned by their parent trees compared with soil conditioned by other *Populus* species, even though the ‘home’ soils were the most N-limited (i.e. highest C : N ratio and highest microbial N pools, Fig. 2). Because parent species affect soil microbial...
Multi-level selection... whose phenotype is it and how is selection acting?

While no experimental approach for multi-level selection is widely accepted, multi-level selection provides an important theoretical framework for understanding how higher level selection may influence individual level evolutionary processes. Multi-level selection is generally defined as variation in an individual’s relative fitness that can be partitioned into within-group and between-group components, with ‘level’ defined by the question to be addressed (Keller 1999; Collins & Gardner 2009). Partitioning variation in fitness is an important approach if we are to model the change in the average value of a specific character across all individuals, in all species, in all communities in an ecosystem (i.e. a phenotype that is common to all organisms in an ecosystem such as biomass, plant and soil nutrient content (i.e. carbon, nitrogen, phosphorous), body size, or offspring). We recognize that ecosystems are more than a set of communities, and that some ecosystem properties would go unmeasured even if every parameter at the community level was assessed. Our approach is only one method of using the flexible Price equation to partition across levels of organization. This approach provides an all-encompassing view of natural selection by recognizing that organisms are embedded not only in a complex abiotic environment, but also a matrix of interacting species whose phenotype is it and how is selection acting?

Consider an ecosystem formed by a set of communities \( C \), in which each community is assigned a unique index \( i \in C \). Each community contains a set of species \( S_i \) and we assign each species a unique index \( j \in S_i \). Each species contains a set of different individual phenotypes \( P_{ij} \), to which we assign each phenotype a unique index \( k \in P_{ij} \). Notice that for our purposes communities are mutually exclusive groups of species and phenotypes within an ecosystem, and species are mutually exclusive groups of individuals within a community. Communities can be defined in different ways depending on the character considered and the interest of the researcher as long as they retain their hierarchical and mutually exclusive nature.

Let \( w_{ijk} \) be the fitness of an individual with phenotype \( k \) in species \( j \) in community \( i \). The average (arithmetic mean) fitness of all individuals in species \( j \) in community \( i \) is \( w_j = E_{P_j}[w_{ijk}] \) (where \( E_{P_j} \) denotes the statistical expectation taken over the set \( A \)). Set \( A \) is a generic set which can refer to phenotypes \( P \), communities \( C \), or ecosystems \( E \). The average fitness of all species in community \( i \) is \( w_i = E_{C_i}[w_{ijk}] \). The average fitness of all phenotypes in the ecosystem is \( w = E_{E}[E_{P_j}[w_{ijk}]] \).

Let \( z_{ijk} \) be the value of the character of interest corresponding to phenotype \( k \) in species \( j \) in community \( i \). The average value of character \( z \) in species \( j \) in community \( i \) is \( z_j = E_{P_j}[z_{ijk}] \). The average value of character \( z \) in community \( i \) is \( z_i = E_{C_i}[z_{ijk}] \). The average value of character \( z \) in the ecosystem is \( z = E_{E}[z_i] = E_{E}[E_{C_i}[E_{P_j}[z_{ijk}]]] \).

Consider the value of the character of interest \( z \) and \( z' \) in times \( t_1 \) and \( t_2 \) respectively. Let \( \Delta z = z' - z \) be the change of the character value from one generation to the next. A species changes when the frequency of the different phenotypes within the species changes over time. A community changes when its constituent species change and/or when the frequency of species changes over time. Finally, an ecosystem changes when the frequency of communities changes over time.

We applied the Price equation (Price 1972; Frank 1998; Gardner 2008) to model the change in the average value of a specific character across a whole ecosystem. In particular, the total effect of selection can be partitioned into among-community, among-species within communities, and among-phenotypes within species of a community (Frank 1998; Gardner 2008):

\[
\Delta z = E_{E} \left[ E_{C_i} \left[ C_{P_j} \left[ \frac{w_{ijk}}{w_i}, z_{ijk} \right] \right] \right] + E_{E} \left[ C_{S_i} \left[ \frac{w_j}{w_i}, z_{ij} \right] \right] + C_{E} \left[ \frac{w}{w_i}, z_i \right]
\]

where \( C_A \) denotes the statistical covariance taken over the set \( A \). Here, we assumed that there is no environmental induction or bias in the transmission of a particular phenotype between generations (i.e. \( E_{P_j}[w_{ijk}\Delta z_{ijk}] = 0 \) but an additional partition could be added to account for such changes (Collins & Gardner 2009).

This equation shows that the change, owing to selection, in the average value of a character across the whole ecosystem during the time considered is given by the sum of three terms. The first term is the covariance between a phenotypic character value \( z_{ijk} \) and its fitness relative to the average fitness of all phenotypes in the ecosystem considered \( \left( \frac{w_{ijk}}{w} \right) \) averaged over all species and all communities in the ecosystem. This term
captures whether phenotypes with higher character value increase or decrease within their species and community and describes the average change in phenotypic composition within species. It represents the change in the total or average phenotype of the ecosystem that can be explained by variation in fitness within species.

The second term is the covariance between the average character in each species (\(z_i\)) and the average fitness of that species relative to the overall average fitness in the ecosystem (\(f_j\)) averaged over all communities in the ecosystem. This term captures whether species with higher character value increase or decrease within their community and describes the change in species composition of a community. The third term is the covariance between the average character in each community (\(z_j\)) and the fitness of that community relative to the average fitness in the ecosystem (\(f_j\)). This term captures whether communities with higher character value increase or decrease within the ecosystem and describes the change in community composition of an ecosystem. Note that covariance between a trait and fitness need not imply that the trait is responsible for variation in fitness (Lande & Arnold 1983). Particularly for more inclusive partitions (i.e., species), strong covariances among traits make correlated responses to selection highly likely. For example, average biomass might change owing to differential extinction of prokaryotes and eukaryotes driven by a chemical with physiological effects functionally unrelated to size. Because phenotypic covariances are often different at different levels, partitioning the Price equation can help expose effects of correlated selection (Collins & Gardner 2009).

Note also that the average within-species selection might often be very near zero if different species are changing in opposite directions. Thus, the degree of inclusiveness, detail, and manner of partitioning must all be chosen carefully to most effectively address any specific question. The Price equation is a ‘statistical tautology’ that follows from the definitions of the phenotype, fitness, and grouping variables (Gardner 2008; Collins & Gardner 2009). As such, it is both general and exact, but does not specify mechanisms or functional forms of selection. The levels-of-selection partition of the Price equation shows how the contribution of natural selection to changes at the phenotype, species, and community levels can be distinguished and combined additively to explain the total change of a character value over time. The equation provides a foundation for creating a theoretical framework whereby changes in the phenotypic composition of a population (evolutionary processes) can affect the species and community composition of the ecosystem (ecological processes) and vice versa through ecological and evolutionary dynamic feedbacks. Specifically, this partition allows us to assess eco-evo feedbacks because it separates the contributions of ecological and evolutionary components to the total change. This allows us to determine how a particular set of evolutionary conditions affects the ecological properties of a community or ecosystem, and vice versa. Such processes may favour one species or community over another (sensu Swenson, Wilson & Elias 2000) resulting in changing patterns on the landscape. The total change in a system will be affected most by whichever covariance is greatest.

**Conclusions**

In this review, we have synthesized evidence from different sub-fields of research to provide a broad conceptual framework in which to consider how evolution may impact communities and ecosystems. We focused on five main issues: (i) Within local populations, intraspecific genetic variation affects community and ecosystem properties, although these effects can be dependent on abiotic and biotic environmental context; (ii) across a species’ range, genetically differentiated populations have different effects on associated communities, showing that evolution in one species can drive community change; (iii) genetically differentiated populations can also co-evolve interactions with other species, resulting in feedbacks and strong patterns of local adaptation; (iv) the effects of feedbacks can alter the environment in a way which affects future generations; and (v) multi-level selection, which provides a framework for considering how the fitness of an individual depends on the group (i.e., population, community, or ecosystem) of which it is a part.

The evidence linking genetic variation and evolution to community change and feedbacks comes from several different approaches whose results have not been synthesized into one conceptual framework, and whose commonalities may not be fully understood. Together, this synthesis suggests that the evolutionary and ecological dynamics of systems are connected through species interactions, specifically indirect genetic effects and feedbacks, and the consequences of this ecological-evolutionary linkage begin with the phenotype of an individual within a population and extend to the associated community and ecosystem. Potential research questions for future studies in this field include: (i) how does the strength of indirect genetic effects and feedbacks change over time; (ii) if a feedback alters the fitness and performance of one species, how does that alter interactions with other species and the ecosystem functions they mediate; and (iii) what are the consequences of multiple feedbacks (i.e., feedbacks from insect herbivores, neighbouring plants, and soil microbial communities) acting on a population simultaneously? Understanding the linkages between evolutionary processes and ecological outcomes is particularly important given the continuing global loss of genetic variation (Butchard et al. 2010), as well as the potential for community and ecosystem-level consequences when large selective events change the range of genetic variation present in a species.
